ABSTRACT

Study Purpose: To review the clearance of 262 patients (453 great toes) presenting with onychomycosis from three private practices that were treated with the PinPointe™ FootLaser™ and a typical clinical protocol to determine outcomes in the percent of responders as well as percent of clear nail growth and lesion reduction in a subset of the patients. These patients were part of the multi-center study submission to obtain FDA clearance to market for the PinPointe FootLaser.

Study Design: In this retrospective study, patients received one treatment using the PinPointe short-pulsed Nd:YAG FootLaser. Before and after photographs of the great toe were taken at baseline and post treatment follow up. Photographs were compared to determine response rate. In addition, planimetry using ImageJ software was used to determine clear nail growth as well as lesion reduction.

Study Results: The percent of patients presenting at long-term follow-up intervals with reduced lesion area were 67.7% at 3 months, 70.5% at 6 months, 76.8% at 9 months and 81.5% at one year. Planimetry showed that in the subset of toes where measurements were conducted there was a 100% response rate. A mean of 78% of absolute clear nail area was achieved with an 181% of clear nail growth.

Conclusions: Results indicate that the PinPointe FootLaser treatment can contribute to the non-pharmacological management of onychomycosis by improving the percentage of clear nail and reducing overall lesion size in clinically diagnosed onychomycosis.

INTRODUCTION

Onychomycosis is a pathogenic infection of the nail that affects an estimated 10-30 million people in the United States alone. In the geriatric population, the prevalence is reportedly as high as 40%. This infectious disease can be severe enough to drive millions of patients per year to seek medical treatment. In the setting of underlying conditions, onychomycosis may lead to more severe sequelae, such as opportunistic infections in the case of HIV and amputation in diabetes. Further, an infected nail serves as a reservoir of disease that can lead to recurrent Tinea pedis. A chronic disease with a high chance of recurrence, onychomycosis is a condition without a cure and in need of methods offering better disease control.

Currently there are two FDA-approved oral antifungal drugs used to treat onychomycosis: 1) oral terbinafine (Lamisil®) and 2) itraconazole (Sporanox®). Oral terbinafine has an efficacy of 35-78%, and itraconazole has consistently lower efficacy. As with any pharmaceutical therapy, these treatments confer potentially serious side effects and drug interactions. In our experience, less than 10% of patients presenting with onychomycosis are eligible for treatment with terbinafine.

In addition to oral antifungal drugs, topical therapies are also indicated for the treatment of onychomycosis. Nail lacquers containing ciclopirox, amorolfine,
in its daily use. Additional foot hygiene instructions were given and patients were followed at approximately three-month intervals. Patient’s used the SteriShoe® product to sanitize their shoes. Great toe photos were obtained of toes before treatment and at followed ups, to a maximum of 10 months post-treatment. The photographs were compared to assess response rate. In a subset of five toes planimetry was used to calculate clear nail growth and lesion reduction.

**PLANIMETRY OF PHOTOGRAPHS**

Patients were included in the analysis if they had a usable baseline photo and at least one useable follow-up photo. The photo had to be of sufficient quality to clearly visualize the extent of the entire nail plate. Planimetry was performed to measure lesion reduction and clear nail growth on a subset of patients.

The total nail plate area is defined by the anatomical boundaries of the hyponychium distally, the lateral folds medially and laterally and the eponychium (cuticle) proximally. The hyponychium is a stationary anatomical landmark and is identified as the distal boundary independent of the variable distal location of the nail plate. In most cases the area bounded by the hyponychium distally and the infected /clear nail boundary proximally is the “lesion.” The area from the boundary to the eponychium is “clear nail.” The boundary between lesion and clear nail was often evident but sometimes ambiguous.

Since this was a retrospective study, the images of the great toe that were submitted for analysis lacked a distance scale and Adobe Photoshop was used to achieve a consistent magnification. Photos were neither enhanced nor filtered hence the margin between clear and infected nail was unaffected.

Using Adobe® Photoshop®, a technician traced the area of clear nail and the area of infected nail. To achieve consistency with measurements and evaluation the following defining criteria was used:

Clear nail was defined with objective criteria as a uniform pink coloring, reddish, flesh or pale; smooth surface and normal thickness. Areas that are slightly discolored but smooth and normal thickness are generally considered clear. Infected nail was defined with objective criteria as a milky white,
black, brown, yellow or occasionally green color. Areas with distal or proximal spikes are considered infected. The nail plate may be smooth but more often flakey, distorted, roughened, ridged and/or thickened. The nail plate may be separated from the nail bed (onycholytic) (Figures 1,2) The photos which outlined the clear and infected nail area were opened in ImageJ software and measurements were taken. The area was calculated in pixels which was then used to represent the area of the lesion at the baseline and the follow up time point.

The baseline lesion area was defined as the total infected area including discoloration, thickening and yellowing of the nail at baseline. The follow up lesion area is defined as the total infected area including discoloration, thickening and yellowing of the nail at the follow up time point. The lesion reduction (% of baseline) was then calculated by dividing the absolute lesion decrease (%) by the baseline lesion area (%).

Student’s T-test was performed and p-values lower than 0.5 were considered significant. Standard deviation was calculated to determine the variation that existed from average.

RESULTS
Patient photos meeting study criteria yielded results from 262 patients. Of these, 51% were male and 49% were female. The mean age of the patients was 53.8 years (range= Ages10-87, SD=14.6). The ethnicity was 90% Caucasian, with an additional 4% Asian, 3% Hispanic, 2% African-American and 1% other. The useable photo sample included 453 great toes that had been treated with the laser.

The percent of patients presenting at long-term follow-up intervals with reduced lesion area were 67.7% at 3 months, 70.5% at 6 months, 76.8% at 9 months and 81.5% at one year.

Increase in Clear Nail Area and Lesion Reduction in Subset of Toes
A subset of 5 toes that were measured by planimetry showed that 100% of patients responded and had an increase in clear nail growth at follow up. The mean baseline clear nail area was 28% (±32%) of the nail. After an average of 7 months post treatment the clear nail area was increased to 78% (±6%) of the nail. Using these two measurements, the clear nail growth (% baseline) was calculated to be 181%. (Table 1, Figure 3).

DISCUSSION
This study evaluated the PinPointe Short-Pulsed Nd:YAG laser as a treatment option for Onychomycosis of the toenail. The PinPointe laser utilizes the 1064 nm wavelength which has the ability to pass through the nail plate into the nail bed of the toe. As a result, the fungal material in the nail bed is heated to very high temperatures which inhibits growth, causes damage, and destroys dermatophyte cells. As the temperature beneath the nail plate increases, chemical reactions that promote fungal cell growth occur less efficiently and growth slows. Eventually as the temperature reaches a certain point, growth completely stops and cell components such as enzymes and cell membranes are damaged by the heat. Hashimoto and Blumen-thal studied the effect of heat on dermatophyte arthropores and found that arthrospores of T. Rubum, the primary dermatophyte that causes onychomycosis, were sensitive to heat treatment. This indicated that heat treatments may destroy most of the dermatophytes and the spores they produce. Vural et al further studied the inhibitory effect of heat on dermatophyte cells. They found that the treatment with the 1064 nm wavelength resulted in a much slower growth rate, indicating that the laser energy was inhibiting the growth of the dermatophytes. They suggested that the 1064 nm might be useful in targeting not only the dermatophyte cells but the blood supply associated with their viability because this wavelength is readily absorbed by Hemoglobin.

Studies evaluating the efficacy of oral and topical antifungal treatments measured improvement and reported data based on complete cure of onychomycosis. The success of topical treatments was low (7% for Sporanox) due to the inability of the medication to reach the nail bed, long treatment time (9-12 months) and dependency on patient compliance.14,16 Efficacy of oral terbinafine was variable (35%-78%) which can be attributed to antibiotic resistance and dependency on patient compliance.8,9,10

In this study, efficacy of the 1064 nm laser was measured based on clear nail growth and reduced lesion area. Both measurements showed a significant improvement with 78% clear nail growth and a decrease in the lesion from 72% at baseline to 22% after an average of 7 months. Treatment also improved the quality of the nail (Figure 2) further
increasing patient satisfaction. When comparing this study to the use of oral and topical antifungals, the use of the 1064 nm Nd:YAG laser has provided an alternative treatment option which has demonstrated significant efficacy.

In addition to a very prominent laser treatment effect, it is possible that long term efficacy of at least 1 year is influenced by the improved medical management changing to appropriate footwear, prescribed regular use of topical antifungal treatments, ways to avoid toe trauma and reinfection is a partial list of advice given to patients in this study. One expects that these will all improve the clinical outcome, although used alone, historically, these remedies have been disappointing. Still, the possible effects of after care treatments should be considered in interpreting these retrospective data. The most conservative conclusion of this study could be that treatment with the laser, embedded in a program of proper management, results in overall improvement in the percentage of clear nail.

The sample in this study represents a cross section of the actual patient population. These were patients with a clinical diagnosis of toenail infection who had elected the FootLaser procedure with patients with a clinical diagnosis of toenail infection of the actual patient population. These were overall improvement in the percentage of clear nail.

CONCLUSION
The use of the 1064 nm Nd:YAG laser has proven to be an effective treatment option for onychomycosis. Patients in this study experienced 181% new nail growth reducing the average lesion from 72% at base line to 22% at follow up. In combination with proper foot care, laser therapy provides an alternative treatment option with rapid treatment duration, no side effects, no blood monitoring and few contraindications.

The mean lesion area at baseline was determined to be 72% (±22%) of the nail and was reduced to 22% (±6%) of the nail at follow up. Based on the mean baseline lesion area and the mean follow up lesion area, lesion reduction was calculated to be 69%. (Table 2, Figure 3).
